ABSTRACT

The Suffolk County (New York) Department of Social Services sponsored a performance study to gain insight into the department's operations. Management science techniques were used to portray operations of the Client Benefit (CBA) and Community Service (CSA) Divisions. The CBA administers public assistance programs, and the CSA provides social services. The CBA and CSA were disaggregated into 187 and 153 workstations, respectively, and a number of distinct actions were analyzed. Approaches used in the evaluation included queueing theory and the marginal analysis model. Solutions were compared for four generated service-demand scenarios for each division. The studies indicated that some solutions proposed in light of the county's budget deficit, such as decreasing the level of services or reducing the number of staff, and alleviating the staffing slack in some workstations, are not feasible because of the steady and unabated rise in the mandated program's caseload, legal regulations, political expectations, and the queueing behavior of the systems. Some actions are suggested to help the department cope with its work flow, but it is noted that these actions will not remedy the situation, but will merely mitigate a few consequences of the continuing rise in service demand. To the Supervisors who identified the stations and matters and to the staff members who recorded their work efforts and work flow patterns, thereby contributing to the initiation of this study.

ACKNOWLEDGEMENTS

Several people deserve an acknowledgement for the substance and detail presented in this study. Special thanks to Dr. Ruth Brandwein, Commissioner and her Executives, Managers and Supervisors for their assistance, encouragement and support. Thanks are also due to the entire staff of the CBA & CSA Divisions for their assistance in the data collection phases.

Also, acknowledgement is due to Selim Akturk and Pu Wang for their valuable computer programming assistance.

Appreciation is due to Doreen Wiggins and Faith Newhall for typing this report. Finally, many thanks go to Peter Streett for editing this manuscript.

SUNY Stony Brook, New York
March 1991

Chapter One INTRODUCTION

Public service delivery agencies in New York, and in Suffolk County (N.Y.) in particular, spend millions of dollars on human services. While these organizations audit how these dollars are spent, they rarely have information about the:

- o Performance and efficiency of these service
 delivery systems' operation;
- o Effectiveness of the services rendered by these systems;
- o Clients satisfaction with the services rendered by these agencies; and
- o Quality of the services rendered by these agencies.

The lack of information concerning these outcome, satisfaction, and efficiency issues can be partially attributed to the prevailing views found in social service settings. Although expenditures on human services are being audited by the state and federal governments, the prevailing notion is that the accounting and management practices used by the public service delivery systems do not lend themselves to evaluation of these issues.

This notion however, has been challenged in the literature inasmuch as proven theories and quantitative techniques have been used to address the satisfaction, outcome and performance aspects of service delivery sytems operation [see Baskin 1974; Beckman 1982; Cordray 1984; Koss 1978; Spottheim 1975; Spottheim/Wilson 1986-1990].

Meanwhile, the rising cost of rendering public welfare services and the concurrent curtailment of federal and state funds to support such services have prompted an ongoing debate regarding the relationship between services rendered and their administrative costs. Lately, this debate has been intensified by the Federal Government's pressure upon local jurisdictions to improve the performance of their federally

^{*} The opinions and findings presented in this report should not necessarily be interpreted as the view or policies of the SCDSS.

Re: The SCDSS Final Report

sponsored programs through the implementation of:

- o An improved workers' activities monitoring procedure;
- o Realistic work standards for such programs; and
- o Staffing policies aimed toward the enhancement of workers' productivity [see Lenov 11/14/87; Mathews, 3/7/88; and Raspberry, 2/23/88 in the Washington Post 2/23/88].

Consequently, the Suffolk County Department of Social Services (SCDSS) has decided to sponsor a <u>performance</u> study first. Management felt that such a study will allow administrators to gain a better insight into this department's operation.

It was also felt by management that since the performance aspects of the SCDSS operation are not intuitively obvious, the SCDSS' administrators would benefit from the findings generated by an analytical study portraying the relationships between administrative resources (e.g., payroll budget and staffing) and services rendered by the two major entities of this department.

Consequently, we have decided to use management science techniques to portray the Client Benefit (CBA) and the Community Service (CSA) Divisions' operation, quantitatively. The CBA administers public assistance programs, whereas, the CSA's obligation is to provide Social Services. Since these service delivery entities do not share identical missions and goals, they provide different types of services, and have different operational structures.

Therefore, we have disaggregated these divisions into their respective components and identified their corresponding set of administrative action; taken by them on behalf of their clients. Thus, the CBA & CSA were disaggregated into 187 & 153 work stations, respectively. Also, 35 & 450 distinct service related matters (actions) processed by the CBA & CSA's systems, respectively, were identified. Primary workflow, work effort and other data were then collected and analyzed for the purpose of providing the SCDSS' administrators and supervisors with a quantitative perspective regarding the efficiency aspects of their systems' operation.

I. THE RESEARCH PROBLEMS

The previously discussed decision making environment led us to conclude that this research study should address the following predicaments:

o How should the "factors of production" (staffing and payroll budget levels) be distributed over the CBA & CSA's stations so as to allow them to process

Re: The SCDSS Final Report

demanded (or anticipated) level of service-related matters <u>efficiently</u>, without altering these systems:

- 1. Operational structure
- 2. Observed processing time of matters
- 3. Work flow patterns (of matters) between stations of these divisions; and
- o What administrative practices could be modified by management in order to enhance the productivity level of the CBA & CSA systems?

II. THE APPROACH

To address these research predicaments, we have used a blend of social services and organizational technology concepts along with complementary management science techniques.

Accordingly, the Client Benefits (CBA) and the Community Services (CSA) Segments of SCDSS have been viewed as two separate service delivery systems. While they contain corresponding bureaus and centers, each division was viewed as an open queueing network composed of supervisory and line (workers) stations (units) which are <u>linked</u> together through the recurrent flow of case records and administrative related matters that must be processed by these units.

Thus, given the level of matters to be processed (under alternative administrative scenarios), the intent behind the application of these techniques (models), was to determine the number of <u>staff members</u> needed to be allocated (or shifted) to each of these divisions' stations. In applying these models, we have <u>exploited</u> existing worker's performance flexibilities found in these divisions while considering alternative payroll budget configurations and other restrictions for the purpose of ascertaining staffing solutions which:

- 1. Assure that the processing of service-related matters, involving a survival-threatening situation of a waiting client, have highest processing priority.
- 2. Assure that the total amount of time spent by a matter in the system is no greater than four weeks.
- 3. Minimize the number of items (or matters) waiting at a station to be processed.
- 4. Minimize particularly the overburdened workload of supervisory stations.

It should be noted that the CBA and the CSA's staff allocation solutions provided by this approach were derived in context of the case-record and matter processing activities, respectively.

Re: The SCDSS Final Report

In summary, the demanded levels of services, the processing time of such services, along with quantitative "snapshots" of these divisions' operational structures, the weekly payroll budgets and the exchangeability of workers' matrices, were used within the framework of the queueing and marginal analysis models in order to:

- o Portray the relationships between the available administrative means (staffing and weekly payroll budget) and the amount of client-related matters processed by these systems;
- o Emulate and streamline the operation of the CBA and CSA systems;
- o Derive current and potential performance (or efficiency) measurements for these divisions; and
- o Derive optimal staffing allocation solutions for these divisions, which minimize the payroll budget and maximize staff utilization simultaneously, under various administrative scenarios.

III. THE THEME & STRUCTUPE OF THIS REPORT

The management science approach used in this study allowed us to reduce the operational elements of the CSA and CBA Divisions and the service-related "matters" processed by these systems into a computer algorithm, portraying the weekly operation and performance of these systems, quantitatively. Specifically, the queueing theory along with marginal analysis techniques [see Gross 1975, Fox 1966] have been employed in These techniques were chosen because of their this study. properties that simplify the construction parsimonious models which are capable of providing voluminous information regarding the system's operation, while using a minimum amount of relevant data.

Since these techniques can emulate the weekly operation of the system, it was felt that they also can be used as the quantitative counter-parts of organizational concepts advocated by Katz and Kahn (1966), March and Simon (1958), Perrow (1972), Thompson (1972), Woodward (1970) and found in the social services literature [see for example Cronbach 1982, Hasenfeld 1972, McDaniel 1978, Newman, 1978 and Vinter 1967].

In addition, these techniques were selected because they can emulate and streamline the workflow relationships between the <u>elements</u> of the CBA and CSA systems. Finally, it was felt that since the relationships between the SCDSS' organizational properties are not intuitively obvious, the SCDSS administrators will benefit from analytical models capable of

portraying the optimal relationships between "outputs" produced and the corresponding resource needs, under various scenarios. Hence, the analysis commenced with the following tasks:

- o Conceptualization of the operational structure and the objectives of the divisions;
- o Disaggregation of these systems' administrative entities into a set of processing stations and the identification of outputs and/or service related matters processed by these stations; and
- o The collection of primary work effort and other work flow data to portray the interrelationships among processing units (stations).

Consequently, the said techniques were used in conjunction with the primary data base to construct Management's <u>Decision Support Models</u> for the purpose of:

- o Providing a quantitative "snapshot" concerning the actual operation of the systems' elements;
- o Identifying existing (and anticipated) congestion and staffing problems; and
- o Enhancing the productivity of both the CSA and CBA systems under different administrative scenarios.

In this report we present the logical and methodological concepts along with the <u>findings</u> of an applied modeling effort undertaken by us while analyzing the operation of the CBA & CSA systems. The paradigm behind this endeavor is a blend of discursive theoretical concepts found in the social service literature and complementary quantitative techniques culled from the managment science literature.

For expository purposes, however, the theoretical, methodological, and applied research concepts employed, instead of the quantitative aspects of this study, are discussed throughout this report. Hence, the remainder of this paper is structured as follows: the Conceptual Overview of Human Service Organizations and the CBA/CSA Systems, in particular are discussed in Chapter II. Chapter III deals with the Methodology of this endeavor. The results of the CBA Analysis are presented in Chapter IV, whereas the CSA's Findings are discussed in Chapter V. Finally, the Summary and Conclusion can be found in Chapter VI.

Re: The SCDSS Final Report

Chapter Two THE CONCEPTUAL OVERVIEW OF THE CBA/CSA OPERATION

For expository purposes, the conceptual overview of the Client Benefits (CBA) and the Community Service (CSA) Divisions are presented below in light of classical concepts regarding; a) social and human services, b) organizations' missions and objectives, and c) organizations' structure and processes.

I. PUBLIC ASSISTANCE AND HUMAN SERVICES

If the services rendered by these systems are perceived to be governmental actions taken in relation to individuals and families, the avowed intent of such services is to assist these clients to return to the position of economic and social self-sufficiency as defined by Morris (1973), Titmus (1968) and Wedemeyer (1970). These actions are executed through a set of Public Assistance, Medical Assistance, Food Stamps and a host of Social Services programs. As the "donor" of these services, the government exercises its power by determining the desired level of health and social welfare of its citizenry, and the eligibility criteria for the beneficiaries (clients) of such programs [see Perloff and Wingo 1968]. Also, the government, as the donor, picks up the cost of services rendered by this service delivery system.

Subsequently, the CBA's delivery centers and the CSA's bureaus were perceived to be "facilities" producing "publicly induced collective services" inasmuch as these services are financed by one segment of society-taxpayers-for the purpose of assisting the client to attain a position of self-reliance. Since the financial revenue of these systems are not derived directly from the services they produced, they are also referred to as non market entities [Fox 1972].

II. THE SCDSS' MISSIONS, GOALS, STRUCTURES AND PROCESSES

While public service delivery organizations are characterized by their enduring operational structure and recurrent administrative processes [Tausky 1977], it was postulated that the SCDSS' missions and goals have contributed (over time) to the development of its current operational structure and processes. In other words, the CBA's centers and CSA's bureaus along with their complementary stations, and the workflow patterns between these stations, have been created and modified by management over time to assure an orderly determination of clients' eligibility, and the provision of mandated services to the eligible.

Also, an earlier exploratory review of the SCDSS' structure confirmed the existence of Tausky's (1977) universal

organizational entities and properties such as:

- o Enduring organizational structure;
- o Identifiable processing stations;
- o Identifiable "outputs" produced (or processed) by these stations;
- o Measurable work effort devoted by a particular station while processing their respective outputs (or service related matters); and
- o Observable workflow patterns between stations [Adapted from Tausky 1977].

The existence of these organizational properties along with the systems' missions and goals, led us to conclude that the interrelationships between these organizations' elements can be analyzed quantitatively [Spottheim 1/24/89].

III. ORGANIZATIONAL TECHNOLOGY

Since the missions and goals have influenced the CBA's and the CSA's operation, the recurrent administrative pocesses (of service related matters) found in these entities can be dubbed as "organizational technology" [see Perrow 1972; Thompson, J.M. 1973; Vinter 1967; and Woodward 1970].

In the public welfare setting, this technology is employed upon and/or in relation to a subject (e.g., client, patient) for the purpose of changing the social, economic, or health status of that subject as was suggested by Hassenfeld (1972) and Vinter (1972).

While different units (within a given service delivery system) may utilize different organizational technologies, they (the units) share two common organization technologies, namely; work process and workflow. The former process denotes "clinical procedures" or internal technology used within a given station. The workflow process on the other hand, deals essentially with the reciprocal relationships that exist between units (stations) involved in the processing of a particular service related matter. In this study, however, the work effort concept was used instead of work process to portray the amount of time spent by a given station while processing a particular matter or output. It was felt that a work process analysis is the domain of review boards and professional associations.

This overview and the chosen methodology, led us to conclude

e: The SCDSS Final Report page 8

that the CBA's centers and the CSA's bureaus must be viewed as "facilities" composed of an open network of line and supervisory stations engaged in routinized and recurrent administrative process. The respective stations of these systems are linked together through the flow of recognizable "products" or matters which are processed sequentially, as mandated by the mission and goals of the SCDSS. Since several units or work stations are sequentially involved in the processing of a particular matter, workflow, work effort and other data, along with the queueing theory could be used to portray the operational (rather than the formal) structure of delivery organization service like any service delivery organization like the SCDSS, quantitatively. Subsequently, a resource allocation method such as the marginal analysis and the queueing theory could be employed to address the performance and productivity problems faced by any service delivery organization containing a stable structure and recurrent administrative processes.

IV. DECISION MAKING ENVIRONMENT

Being non-market firms whose operational budget is derived from public sources, service delivery organizations have little external or market pressure of utilizing their resources efficaciously. In contrast, firms operating in a market economy, must produce and allocate their resources efficiently if they wish to survive in an avaricious and market centered economy [Fox 1972]. Such firms are viable as long as their revenue is greater than their expenses. On the other hand, public service delivery entities do not face such challenges; they can always use the options of requesting additional funding or reducing the quality and/or level of a result of this operational services provided. As environment, interest was developed around the evaluation of service delivery systems through the application of Decision Support Analysis or management science techniques that can be used by management to handle the <u>universal</u> <u>administrative</u> problems of:

- o Assuring the realizations of system's goals through the processing of service related matters efficicaciously; and
- Coping with the continuous challenge of persuading service providers, legislators, and interested groups alike to forego their intrinsic opinions and discursive theories regarding the system operation, thereby allowing management to pursue efficiently the collective missions and goals of the organizations in question, [adapted from Tausky 1978].

Re: The SCDSS Final Report

V. PORTRAYING THE SYSTEM'S OPERATIONAL STRUCTURE

While the observed structure and processes were created by management to assure an orderly operation, relevant indicators portray the systems' operations to needed However, contrary to the prevailing notion performances. that: a) caseload, b) number of clients seen, and c) number of cases processed, can be used to measure the system's workload, these data items cannot be used in conjunction with the said techniques [Spottheim 1975, Spottheim & Wilson, 1986-1989]. Since the CBA and CSA systems have been viewed as two mutually exclusive open queueing networks, these items are insufficient to portray these systems' operations quantitatively because:

- They seldom "visit" (or are handled by) more than two stations of systems, and as such, they cannot be regalded as the system's "common flow units" or items which generate a system response and require system resources at a number of stations over a longer period of time; and
- o The time and effort devoted by the "unvisited" stations therefore, cannot be "captured" even though they play a major role in the paperwork processes of services requested by eligible clients.

These modeling problems, however, have been avoided by defining an alternative set of "common work flow items."

Hence, to portray the CBA and CSA operational structures and to emulate their processes accurately, we have defined an exhaustive set of administrative processes or <u>actions</u> taken by the stations, in relation to the services requested. These common flow items (actions) are also referred to as "service and management related matters." By using these <u>matters</u> as the models' common flow items we were able to identify the transactions (of matters) between stations which are rarely being "visited" by clients and case records.

Also, these common flow items enabled us to estimate the cumulative time devoted by stations involved <u>directly</u> or <u>indirectly</u>, in the provision of services. Specifically, by "tracing" the flow of matters between stations quantitatively, we were able to emulate situations in which service-related actions (or matters) were initiated in one station and transferred to other stations for further processing, and consequently returned to the originating station.

Chapter Three MODELING METHODOLOGY

The springboard of this applied research study are recently developed models portraying the relationship between public service means (resource) and ends (outputs) developed by the authors [see Spottheim/Wilson 1986-1989, March and June 1990]. The premise behind these, and the current study in particular, is that the performance and productivity problems faced by service delivery organizations can be resolved through the application of management science techniques. Although it is recognized that a performance study should address both the efficiency and performance aspects of service delivery [Cordry & Tuttle 1984], this applied study deals with the efficiency Therefore, this study does have certain Since this approach deals with the efficiency aspect only. limitations. aspects of resource (staffing & payroll budget) allocation within the SCDSS, it ignores the service delivery issues of:

- o Client/worker relationships;
- o Effectiveness of the services rendered by this department;
- o Clients' satisfaction with the services rendered by the CBA and CSA segments of this department; and
- o Quality of the services rendered.

However, unlike the <u>conventional evaluation</u> approach, which focuses on the estimation of "central tendency" of service delivery sytems' production function and comparison thereof, across various organizations, the <u>management science</u> approach is based on the application of management decision support techniques to analyze the performance of a <u>single</u> service delivery system. The premise behind this approach is that the mix of financial and staffing resources can be adjusted so as to approach the "production possibility frontier." This methodology, therefore, provides optimal or "extreme" (rather than "central tendency") staff allocation solutions to problems faced by a <u>single</u> service delivery organization.

I. CONVENTIONAL EVALUATION VS. MANAGEMENT SCIENCE APPROACH

Historically, two major methods have been used to evaluate the performance of non-market firms: the conventional evaluation, and the management science approach.

A. The Conventional Evaluation Approach

Early evaluation efforts were based on the <u>controlled</u> <u>experiment</u> principle as was advocated by Campbell and Stanley (1963) in their classical book. Rather than evaluating the welfare programs in context of their operational structure, Campbell and Stanley (1963) advocated the search for causal relationships through the application of "controlled experiment" and "internal validation" principles.

More <u>recent</u> evaluation studies seem to emphasize a particular "school of thought" or a research paradigm (Cronbach, 1982), hence, they tend to examine:

- o Welfare philosophy schemes;
- o Political, sociological or psychological processes observed in the systems; and
- o Narrow phenomena while using case study and/or "expost facto" method of investigation.

According to Cronbach (1982), these types of studies tend to be "micro and anecdotal" in nature, and as such they have little application to the management and operational problems faced by the systems. Even Mary Parker Pollett's classical view that management is a process of "getting things done efficiently, through people" [cited in Lee, 1983], seems to suggest that the conventional evaluation is an inappropriate approach for examining productivity problems faced by service delivery systems.

Meanwhile, interest was also developed around the application of econometric methodologies to explore the politico-economic aspects of social and health service programs (see Booms 1973; Cohn 1972; Feldstein 1971; Madden 1972; and Yett 1971).

B. The Management Science Approach

Management is defined as a dynamic decision-making process, which efficiently reconciles human, financial and physical resources for the purpose of "producing" a desired level of outputs [Lee 1983]. Management Science, on the other hand, is a complementary discipline whose <u>aim</u> is to provide management with decision support information regarding:

- o Organizational problems which are not intuitively apparent;
- o Efficient ways of realizing the organization's production objectives; and

o Feasible courses of action that can be used to streamline the system's operation [Lee 1983].

In sum, the limitations of the evaluation and the econometric studies have led researchers and administrators alike, to explore the applicability of methodologies that can be used to analyze properties such as the structure, processes, outputs service delivery outcomes of entire Consequently, authors such as Hassenfeld (1972); Mantel et al, 1975; McDaniel (1978); Natale (1981); Newman (1978); Rossi (1978); have advocated the application of these approaches in a social services setting, whereas, Baskin (1974); Melone (1988); Spottheim (1975); Spottheim & Wilson (1986-1989) and others, have demonstrated the application of management sciences techniques to the performance and productivity problems faced by a variety of service delivery systems.

II. DATA REQUIREMENT

The application of the said techniques presupposes that the systems in question have a readily available work standard and work flow data. While such information is available in industrial setting, social service delivery systems seldom have a reporting system for tracking how workers (affiliated with a given station) spend their time while processing their respective services and/or matters.

Hence, to address the aforementioned research problems it was necessary to conduct two (self reporting) surveys for the purpose of collecting primary work flow, work effort and other data concerning the operation of the CBA & CSA Divisions. The work efforts information was then transformed into work standards, whereas the work flow information was used to portray these systems' operational networks, quantitatively. Consequently, the two data bases of this study were constructed so as to include numerical information regarding the:

- o Work effort (work standard) measured in minutes, devoted by these division's stations to process their respective matters;
- Weekly arrival rate of matters to the CBA's Centers and the CSA's Bureaus and consequently, to each station of these entities;
- o Work flow patterns of matters between the stations of these systems;
- o Worker's performance flexibility (exchangeability)
 matrix;
- o Estimated Weekly payroll by station; and
- Current staffing by station.

Subsequently, this data base was used in conjunction with the queueing and marginal analysis theories [see Gross 1975; Fox 1966] for the purpose of portraying the CBA and CSA operation, quantitatively.

III. THE MANAGEMENT SCIENCE TECHNIQUES USED IN THIS STUDY

Health and Welfare Officials have recognized recently that the current research, planning and evaluation methods found in the social services literature are inappropriate to address the performance and efficiency aspects of service delivery system operations, namely:

- o Definition and classification of outputs or services;
- o Administrative structure and processes;
- o Costs of operation; and
- o Optimal utilization of staff.

The inadequacy of these methods can be partially attributed to the fact that the theorists, practitioners and researchers alike tend to use discursive theories to address these aspects. The problem with the discursive theories is that they provide no rigorous relationships between propositions [Tausky 1977]. Also, this research environment has been exasperated by the fact that public service delivery systems are viewed by researchers as merely "human treatment, or processing organizations," [see Hassenfeld 1972; Vinter 1967; Beckman 1982; and Mantel 1975] rather than service delivery systems. Thus, many of the evaluation studies are based on seemingly competing theoretical concepts such as:

- o Exchange and conflict;
- o Integration, coordination, interface, and linkages;
- o Organizational technology; and
- o System's and its external environment interrelationships [see Spottheim 1974, 1975, 1985].

While the theoretical concepts seem to be a collection of competing items, in reality, many of them have been consolidated into the mangement science theories.

However, the management science techniques used in this study and discussed below, deal with <u>performance</u> and <u>efficiency</u> aspects of production, and as such, they ignore individual's behavior. Therefore, employees are regarded by these theories as <u>needed</u> "factors of production" for realizing the mission and goals of the organization in question, through the performance of assigned tasks [March & Simon 1958]. Therefore, the more tasks a worker can perform, the higher the <u>efficiency</u> potential of the system in question.

A. The Queueing Theory

Since its inception by Erlang (1917), queueing theory has been used to study the random arrival of items, subjects, or matters to be processed at a processing facility of limited capacity [see Gross, 1975]. In applying this theory to the problems at hand, we assumed the CBA's centers and the CSA bureaus are operating as an "Open Jacksonian Queueing Network" [Jackson 1963] inasmuch as they have no control over the weekly arrival rate of matters to be processed at a particular center or bureau. In using this theory it was also assumed that management is striving toward a steady state operational protocol - characterized by:

- o A "poisson" process dictating the arrival rate of matters to the systems, and subsequently, to individual stations for processing purposes;
- o A processing time, (of any matters) which follows an "exponential probability" distribution, reflects the variety of matters processed at most stations as validated empirically;
- o A mean arrival rate which is <u>less</u> than the mean processing rate of matters;
- A network of stations, which the matters must move through while being processed sequentially, where each station contains one or more parallel service channels; and
- o A "calling population" (e.g., arriving clients/cases/matters) which is "infinite;" i.e., the arrival process is not perceivably reduced by having one more arrival to the system.

B. The Marginal Analysis Model

The premise behind the application of Fox's (1966) Marginal Analysis model is the notion that the staffing mix across all of the processing stations can be adjusted so as to accomplish an efficient allocation of staffing resources to achieve desired or demanded "production" targets, for matters over the long run with minimal administrative delay to the matters before final determination is rendered. Hence, given the desired processing level of matters, the intent behind the application of this model was to determine the number of workers needed to be allocated to each station.

Re: The SCDSS Final Report

Concurrently, efforts were made to:

- o exploit existing workers' performance flexibilities;
- o minimize total operational cost (e.g., wages &
 salaries); and
- o assure that the amount of time spent by a matter in the system is no greater than four weeks.

In other words, we have tried to find how to <u>efficiently</u> allocate the weekly payroll budget so as to optimize an administrative performance measure based on the timely disposition of service related-matters. Thus, the formulated marginal analysis model contains an <u>objective function</u> and a set of inequality <u>constraints</u> regarding the amount of time the various matters <u>spent</u> in their respective stations. The sum of the (average) time spent by a given matter at each of the stations it visited, was pegged to be <u>less</u> or equal to a <u>four week</u> period. In addition above, it was necessary to:

- o specify relationships between time spent by matters at their respective stations and the processing capacity of these stations; and
- o identify compatible worker and supervisor classes that can be interchanged.

Since the average time spent by a matter at a service station is inversely proportional to the processing <u>capacity</u> of that station, this relationship is <u>not</u> a <u>linear</u> one. Therefore, the capacity was estimated through the application of the queueing theory and this model. In doing so, it was assumed that the processing capacity of a station can be expanded <u>only</u> by increasing the number of workers of that station. This assumption was made in concurrence with our research aim of enhancing the productivity level of this Division <u>without tampering</u> with the observed work standards.

To determine the optimal number of workers at each service station, several interchangeable worker/supervisor classes were identified. When additional capacity was required by a given station, the model's algorithm assigns an available worker, whose hourly wage rate is equal to the lowest rate within the class of still available workers.

Re: The SCDSS Final Report

The logic that drives the marginal analysis optimization, in short, is getting the most "bang for the buck." A worker of a certain grade level, therefore, is assigned to a particular station if the expected waiting time or length of queue (of matters waiting to be processed) in that station is shortened more than any other station where the worker may be placed. If a worker is taken away from one station and placed in another, it is because the decrease in waiting time (or length of queue) at the station to which the worker is assigned is greater than the waiting time increase at the station from which the worker is taken.

For the so called "minimum cost" (or "lean payroll budget configuration") solutions, whereby only the minimum staffing is allowed to meet work requirements, the assignment of workers are made to a station until the production capacity just exceeds the inflow of work to the station. In addition, the <u>four week</u> limit time for matters in the system is also enforced.

Since the queueing and the marginal analysis models were used to estimate the <u>long run</u> optimal weekly payroll budget and staffing requirements to process a given level of matters, we have specified these models so as to exploit the CBA and CSA operational flexibilities and consider these systems' constraining factors simultaneously, while deriving the optimal staffing solutions for the systems.

IV. THE RESULTS

The application of Fox's (1966) model in conjunction with this study's data bases mentioned earlier enabled us to generate descriptive and prescriptive results concerning the operation and performance of the two systems. Specifically, the application of this approach allowed us to generate a uniform set of estimated results (by station) for several research scenarios, namely, the:

- Station Number
- 1. Weekly arrival rate (of matters) to the station
- Weekly services (or processing) rate per worker by station
- 3. Present utilization index
- 4. Optimal utilization index
- 5. Average number of itmes waiting in a station's queue before being processed by that station
- 6. Worker's grade
- 7. Present staffing (by worker's grade)
- 8. Staffing after shifting

9. Optimal staffing (by grade)

A. Results' Description

Since the <u>nine</u> items listed above may not be familiar to the readers of this report, we provide below brief definitions thereof:

- The weekly arrival rate to a station is the 1. sum of service related matters arriving (to a given station) from the "rest of the world" or from another station within the center or bureau service area for further processing. This arrival rate presupposes that the length of the working week is equal to 35.5 working In contrast, the weekly arrival rate to the system reflects the (weekly) client's demand of service-related actions or matters to be processed by the CBA. Since several stations are involved in processing demanded matters (for each arrival to the system), the arrival rate to the stations on average is higher than the arrival rate to the system.
- 2. The weekly service rate (processing) per worker, denotes the expected number of items (associated with any type of matter) that can be processed by a worker affiliated with the given station. This rate was based on a 30 hour work week. The remaining 5.5 hours were considered to be vacation, sick leave, holiday, and breaks.
- Present utilization index is defined as the 3. proportion of time, workers (affiliated with a given station) were found to be busy (i.e., actively engaged) in the processing of one (or more) of the CBA or the CSA's matters. utilization index greater than one (1) implies a congested (or bottleneck) station and as such this station may contribute situation where related downstream stations are "starving for work." The bottleneck problems have been mitigated by adding a "server" or worker to that station. Since the arrival rate to cach station was captured during a short period of time, it gave us a "snapshot" of system operation, during that period. present utilization index greater than one (1) implies that either:

- o Workers must work overtime to prevent a buildup of matters on their desk;
- o Workers must be temporarily shifted from other stations to prevent this buildup;
- The arrival rate actually represents a "peak" in cycle and the present staff members may "work off" the buildup during a subsequent "valley" in the cycle; and
- o In any case, a utilization index greater than one is not a "steady state" phenomenon and must be interpreted as a transient statistic that must be remedied in one of the aforementioned ways.
- 4. Optimal utilization index is the estimated proportion of time that workers are actively engaged in processing matters arriving to the station after an optimal reallocation of staff. This index was not allowed to be greater than 0.99.
- reflects the expected number of case records waiting in a station to be processed under a steady state operational environment. This variable was used in the CBA's study as the objective function to be minimized, whereas in the CSA's study, the average waiting time spent by a matter in a station was used as the objective function.
- 6. <u>Worker's grade</u> depicts the civil service grade level(s) found in the station.
- 7. <u>Present staffing</u> is the current assigned number of workers by grade to each station.
- 8. Staffing after shifting reflects the number of staff members at each station after staff reallocation using marginal analysis without releasing any workers. Under the lean (minimum) an reduced payroll budget configurations, this variable may have a value which is higher than the optimal staffing solution (see Item I).

9. Optimal staffing reflects the "best" distribution of workers by grade (across all stations) which will assure the timely disposition of matters and may require hiring or releasing workers (especially in a minimum cost or lean budget scenario).

Since the <u>results</u> generated by the management science approach can tell us what performances and/or productivity levels are attainable and what cannot be expected from the CBA and CSA systems, other experiments with alternative administrative structures are not necessary. Instead, corrective courses of action to enhance the performance and productivity of this service delivery system could be inferred from the findings generated by the marginal analysis model in particular, as discussed earlier in this Chapter.

B. Results' Formulas

Recall that the management science techniques used in this study are parsimonious in nature and as such, they provided us with voluminous amount of information derived from minimum number of statistically validated variables. Therefore, several of the estimated results listed above can be replicated numerically through the application of formulas. These formulas are found in any text on queueing theory and they can be used by management to monitor and adjust staffing needs by stations.

Chapter Four THE CLIENT BENEFITS ANALYSIS

The Client Benefits Division's obligation is to administer a host of administrative and client-related matters associated with the rendering of a public assistance program's mandated services.

Being a local service delivery system whose missions and goals are well defined, this Division's operation has been constructed to aid clients in achieving a state of economic and social self sufficiency through the provision of Public Assistance Services.

I. THE CBA'S MISSION, GOAL, STRUCTURE AND PRODUCTS

Although its operational structure has been recently modified, the CBA's centers and their corresponding work-stations, along with their work-processes and the work flow patterns between these stations, were designed and modified by management for the purpose of assuring an orderly determination of clients' elgibility and the provision of mandated services to the eligible.

A. The Mission & Goal

As a service delivery system, the CBA determines clients' eligibility and administers services mandated by the following programs: a) Public Assistance, b) Medical Assistance, c) Food Stamps, and d) Heat and Electrical Assistance Program (HEAP). According to the CBA's management, the mission and goal of this system can be summarized as follows:

- o <u>The Mission</u> of the CBA is to provide mandated programs' services to the needy and poor population of Suffolk County; and
- o <u>The Collective Goal</u> of these Public Assistance programs and their respective services is to help the eligible clients <u>attain</u> and <u>retain</u> economic self sufficiency for themselves and their families.

B. Enduring Organizational Attributes

Although the above mission and goal have periodically prompted structural changes in this Division, certain organizational attributes and properties have endured in the CBA, namely:

- o Recognizable organization structure;
- o Identifiable processing stations;

Re: The SCDSS Final Report

- o Identifiable "outputs" produced (or processed) by these stations;
- Measurable work efforts devoted by a particular station while processing their respective outputs; and
- o Routinized (recurrent) work flow patterns between stations [Adopted from Tausky 1977].

In addition to these properties, each of the stations of both the current and restructured systems seem to be specialized in the processing of a particular matter associated with the programs. Hence, a given station will process a particular matter associated with the arriving case records of a particular program, whereas the subsequent station will handle another related matter. Because of these unique administrative processes, the CBA operation was evaluated in context of its <u>case record</u> processing activities.

C. The CBA's Products

Recall that the stations of both the <u>current</u>, ("old") and the <u>restructured</u> ("new") CBA's systems are linked together, administratively, through a flow of recognizable products or program and administrative related <u>matters</u> which are processed sequentially, as implied by the mission and goal of this Division. Although the CBA has been recently restructured, both the "old" and the "new" systems shared the obligation processing of a common set of matters associated with the incoming program's related case records. These matters are defined in <u>Table I</u>.

A cursory examination of this table will reveal that it contains 37 program and administrative related <u>actions</u> (or matters) taken on behalf of the clients affiliated with federally and/or state-sponsored programs such as:

- 1. Aid to Dependent Children (ADC)
- 2. General Public Assistance (HR)
- 3. Emergency Assistance (EA)
- 4. Medical Assistance (MA)
- 5. Heat & Electrical Assist. Program (HEAP)
- 6. Food Stamps (FS)
- 7. General Administrative & Mgmt. Activities (ADMI)

II. AN OVERVIEW OF THE CBA ANALYSIS

The theoretical concepts discussed thus far and the <u>universal</u> organizational attributes in particular, were used as the conceptual formulation for this analysis. Consequently, the

Re: The SCDSS Final Report

said management science techniques were used in conjunction with the CBA's data base to generate descriptive and prescriptive information regarding this system's performance and operation. The information generated by these techniques includes: a) work standards, b) processing time, c) costs, d) weekly arrival and processing rates, e) current and optimal staff utilization index and f) optimal staff allocation solutions under alternative administrative scenarios.

To generate this information for both the current ("old") and reorganized ("new") operational structures of the CBA, it was necessary to view these systems as two separate queueing networks, even though they share some common operational elements. Specifically, both of these systems are composed of supervisory and line (workers) stations which are linked through the recurrent flow of recognizable together administrative and program-related cases that sequentially processed by these stations.

Hence, given a particular <u>weekly arrival</u> rate of case records to these systems' centers the intent behind the application of the said models was to determine the number of staff members needed to be allocated (or shifted) to each station, under various scenarios.

A. Data Estimation

To address the aforementioned research problems, and subsequently the scenarios discussed below, it was necessary to collect primary work flow, work effort and other data concerning the operation of this Division. Consequently, the data base for this analysis was constructed so as to include numerical information identified earlier in Chapter Three, Section II.

However, due to coding problems found in the Public Assistance Programs' work flow data, it was necessary to approximate the weekly arrival rate of case records (cases) for the Islip and Huntington Centers, in particular, [see Spottheim/Wilson, June 1990]. It was found that the ratio of hourly arrival rate of a particular program's cases to the caseload for that program at a center was extremely consistent across centers with some deviation at Islip and Huntington. Thus, the hourly arrival rates of these centers were adjusted such that they, too, would possess the characteristic ratio processed by all other centers. These ratios by (PA) program were estimated to have the following values:

			<u>Ratio</u>
1.	Aid to Dependent Children (ADC)	0.0155
2.	General Public Assistance (HR)	0.0155

Re: The SCDSS Final Report

3.	Emergency Assistance (EA)	0.0155
4.	Medical Assistance (MA)	0.0131
5.	Heat & Electrical Asst. Prog. (HEAP)	0.0155
6.	Food Stamps (FS)	0.0031

For expository purposes, let us assume that the ADC caseload of a <u>center</u> is 1000 cases. This center's <u>hourly</u> arrival rate of ADC cases is obtained by multiplying its caseload by 0.0155 (1000 \times 0.0155 = 15.5 cases/hr.). By multiplying (15.5 \times 35.5), one will get the weekly arrival rate of 550.2 cases.

In addition to these ratios, it was necessary to estimate the arrival rate of cases to each center of the restructured (new) CBA system, and consequently, to the corresponding stations of these centers. To ascertain these arrival rates, we have used administrative CBA's data concerning the (PA) programs' By applying the estimated ratios caseload by center. mentioned above to the center's caseload (by program), we were able to estimate the weekly arrival rate of cases (by program) to each center. Subsequently, the arrival rate of matters to each station was estimated and the operational structure of animated quantitatively. CBA system was Consequently, efficiency aspects embedded in scenarios 2-4 were analyzed.

B. The Scenarios

Recall that the Research problems mentioned in Chapter I, were addressed through the estimation of staffing solutions for various scenarios. In other words, the management science techniques were used to ascertain optimal resource (payroll budget & staffing) solutions under various operational scenarios. For expository purposes, however, the results presented in this chapter are confined to four scenarios, concerning both the "old" and the "new" CBA systems, hence:

- provides "steady state" solutions for a Case 1 situation in which management wishes to know how should the present level of production (e.g., weekly of payroll budget and staff) be distributed over the "old" CBA's stations, thereby allowing this system to process a weekly rate of program administrative cases observed during the Fall of 1989, in the most efficient manner.
- Case 2 provides steady state solutions for a situation in which management wishes to

know the optimal distribution of staff members over the "new" CBA's stations so as to allow this <u>restructured</u> system to process efficiently, an observed <u>increase</u> over 12% in the weekly arrival rate of cases and matters (observed in May 1990).

- Case 3 provides steady state solutions for a situation in which management wishes to know the optimal staff allocation over the "new" network of stations so as to enable them to process the recently observed (May 1990) cases arrival rate under a "lean" budget configuration (e.g., minimum cost solutions).
- Case 4 provides steady state solutions for a situation in which management wishes to know the; a) amount of cases that can be processed (per week) under a restricted weekly payroll configuration which is five percent (5%) below the Fall 1989, payroll budget, b) weekly corresponding amount of staff members needed to process the said arrivals, and c) the optimal distribution of these workers across all stations of the "new" system.

We mean by "steady state solution" in the foregoing, a solution to a system whose defining parameters are <u>stable</u> and predictable in a statistical sense. We do not mean a system that has been rendered deterministic; rather, the variability has been modeled (accounted for) explicitly. Finally, the reader should note that Case 1 deals with the old structure, whereas the remaining cases deal with the recently <u>restructured</u> (new) CBA System.

C. Modeling Methodology

Since the Fox's (1966) model used to address these four cases, must have a <u>single</u> objective function and numerous constraints, we have designated the <u>number</u> of cases <u>waiting</u> to be processed at each station to be the <u>objective function</u> to be minimized, whereas, <u>the constraints</u> (or rules of operation) of this model were specified to:

o exploit existing worker's performance flexibilities, thereby, allowing us to transfer workers from a given center's station to any other station of the system;

- o assure that the amount of time spent by a matter in the system is no greater than <u>four</u> weeks;
- o assure that a service or a matter which involved a survival-threatening situation, and/or client waiting for services, be processed immediately; and
- o mitigate congestion problems found in supervisory and line (workers) stations due to overburdened workload.

These rules were incorporated into the model's computer programming to assure that the system's productivity enhancement solutions are ascertained without tampering with the; a) work standards, b) organizational structure and c) work flow patterns as indicated by actual observation of the system.

Therefore, we assumed that the processing capacity of a station can be expanded by increasing the number of workers at that station. On the other hand, workers affiliated with a station whose utilization index was found to be <u>low</u>, were <u>transferred</u> to congested stations, if possible, as indicated by the worker interchangeability matrix. The number of workers added to a <u>congested</u> station was determined by taking into account the necessary number of workers to minimize the waiting time a matter must spend at the station, as well as any additional workers that may be required to assure that matters needing action at the station are assured of clearing the system in four weeks. Finally, the system's efficiency was measured in terms of the stations' <u>utilization index</u>.

D. Solutions Provided

The four scenarios (cases) mentioned earlier, represent a handful of administrative situations that have been analyzed through the application of the marginal analysis (resource allocation) model, in particular. The application of Fox's (1966) model in conjunction with the CBA's data base enabled us to generate descriptive and prescriptive results concerning this system's staffing needs and performance. Specifically, this approach allowed us to generate a uniform set of numerical results (by station) for each scenario, namely, the:

- Station Number
- 1. Weekly arrival rate (of cases) to the station
- Weekly services (or processing) rate of cases per worker by station
- 3. Present utilization index
- 4. Optimal utilization index
- 5. Average number of items waiting in a station's queue

Re: The SCDSS Final Report page 26

before being processed by that station

6. Worker's grade

- 7. Present staffing (by worker's grade)
- 8. Staffing after shifting

9. Optimal staffing

Since these result items were defined earlier in this report, that will not be redone in this Chapter. In addition to these resource allocation results, the findings of miscellaneous analysis concerning the <u>old</u> system are provided in this Chapter.

Also, it should be noted that the solutions provided by the models were calculated in context of the CBA <u>case record</u> rather than matter processing activities. Finally, the solutions for scenarios 2-4 are <u>animated</u> results inasmuch as the restructured CBA was not in operation at the time of this analysis.

E. Descriptive Information Generated

In addition to the above solutions, descriptive information regarding the CBA operation and performance has been produced for expository purposes. Thus, several tables containing descriptive information concerning the system's operation, have been included in the Addendum of this report.

III. A STAFFING SOLUTION FOR THE "OLD" CBA SYSTEM

Although this Chapter deals with the estimation solution for the four administration scenarios mentioned above, the solutions presented in the section are confined to the first scenario (Case I) only. In other words, the resource allocation solution (e.g., weekly payroll budget and staffing) are for the "old" CBA operational structure that was in existence during the data collection phase of the Fall of 1989. The CBA system at that time, was composed of nine centers and 187 corresponding stations. These centers are:

- 1. Islip
- 2. Coram
- 3. Smithtown
- 4. Huntington
- 5. Riverhead

- 6. Mastic
- 7. Amityville
- 8. Patchoque
- 9. Wyandanch

The centers and their complementary stations along with the approximated average weekly salary per worker are listed in Table II, whereas, the administrative and program related matters are precluded from this section, inasmuch as they were listed earlier in Table I.

CBASTA

Re: The SCDSS Final Report

A. Case I - Solutions

Solutions for <u>Case-1</u> are tabulated by centers, in <u>Table III</u>. A cursory examination of this table will reveal that it contains <u>nine</u> columns of numerical information concerning the solution items listed earlier. A further examination of this table will reveal that the system requires 449 workers and a weekly payroll budget of \$219,209 in order to achieve a steady state operational environment. In contrast, this system's staffing level was 446 workers, in the Fall of 1989.

Also, notice that the <u>optimal</u> staffing listed in Column I is different from the <u>present</u> staffing (see Column B). For instance, the present staffing for station No. 5 is composed of 5 grade 15 workers, whereas, the optimal staffing solution calls for 2 (grade 15) workers, therefore, 3 (grade 15) workers were transferred to other stations. Also, notice that upon transferring these 3 workers (to other stations) the optimal utilization index was raised to .693 (from the present index of .277), without affecting the length or queue of matters waiting to be processed. A comparison of the <u>current</u> utilization against the optimal indices will reveal that the latter indices have a higher value than the former. Ideally, the optimal utilization indices should have a range of 0.55 to 0.90.

Some stations, however, have a current utilization index which is greater than one. For example, the insufficient current staffing of Islip Center's Station No. 11 causes <u>congestion</u> in that station, and a very <u>high</u> "present utilization" index (2.142). This high "present utilization" implies that this station requires a staff of 3 persons, rather than the current one (grade 8) worker in order to comply with a steady state operational environment, mentioned earlier.

Moreover, numerous Coram Centers' stations are congested inasumch as their <u>current</u> utilization index is greater than <u>one</u>. For instance, station 28, present utilization index is 1.140. By transferring an additional worker to this station, this index was reduced to .570. In addition, it was found that several of the Smithtown Centers' stations were also congested. To eliminate the congestion, it was necessary to transfer and/or hire additional workers.

To mitigate other congestion problems, workers were also transferred, from stations where utilization indices were found to be low, to selected overburdened stations at Huntington, Riverhead, Mastic and Amityville Centers.

In sum, Fox's (1966) resource allocation model, used in this

Re: The SCDSS Final Report

case, tends to equalize the <u>workload</u> of the stations and the length of queue of matters waiting to be processed, through the reassignment of unbusy staff members to the busiest stations. The staff reassignment criteria were specified in the staff exchangeability matrix. Finally, this analysis indicates that the busy stations are composed primarily of QC Examiners, Clerical Staff, and very few supervisors.

IV. STAFFING SOLUTIONS FOR THE NEW CBA SYSTEM

Although the CBA operational structure has been streamlined several months after the completion of the data collection phase, we have decided to <u>animate</u> the new CBA operation and derive staffing solutions from the existing data base. It was felt that results generated by this <u>animated</u> analysis will provide management with information concerning the expected performance of the "new" CBA system.

Since the new CBA was not in operation at the time data was collected, it was necessary to conduct a transitional analysis for the purpose of deriving <u>animated</u> staffing solutions for problems identified earlier by scenarios (cases) No. 2-4, in particular. In doing so we assumed that the new system will continue to handle the program related matters listed earlier in Table I. For exploratory purposes we postulated that the new CBA system will be composed of the following administrative entities or service centers:

1.	Bayshore	5.	Riverhead
2.	Coram	6.	Mastic
3.	Smithtown	7.	Patchogue (defunct)
4.	Huntington	8.	Wyandanch
	•	9.	Chronic Care

These entities (centers) along with their complementary stations are identified in <u>Table IV</u>. The stations' composition in each of the newly created centers were derived through an extensive analysis of both the "old" and "new" centers' caseload, arrival rate of cases, existing and anticipated work flow patterns between these stations. This analysis suggested that the newly structured:

- o <u>Bay Shore</u> Center should have 31 processing stations formerly associated with the defunct Islip and Amityville Centers;
- o <u>Wyandanch</u> Center should have stations which are analogous to those found in the Hungtington Center;
- o <u>Chronic Care</u> Unit is likely to provide MA and an <u>array</u> of related (PA) services to its clients. Although we recognized that this unit's mission is to provide determination and recertification

. Table IV The Restructured CBA's Centers and Corresponding Stations

The "Station Code and Name (Tentative)" column indicates the set of stations used in the study; whereas, the "Station Name (Final)" column indicates the final configuration of stations within the Chronic Care Unit.

Re: The SCDSS Final Report

services to medicaid clients who have long term care needs, the (MA) workflow data analysis suggested that these clients are likely to request additional (non-medical) services. For exploratory purposes, therefore, it was decided that this unit should be composed of 31 stations as indicated in Table IV.

The chronic care unit was subsequently finalized by management into a structure which is different from the one used in this study. Since this analysis suggests that the (non-medical) activities or matters processed by stations not in the final list must be processed somehow, the reassignment of seemingly surplus workers affiliated with these non-existent stations to the appropriate centers should be determined by management. Otherwise, a shortage of staffing is likely to occur in certain centers.

Finally, although the new CBA plan calls for the abolishment of the Patchogue Center, 18 of its workers were retained as a "slack or pool" of workers that can be reassigned by management to other stations during the transition from the "old" to the "new" system. These workers are identified by grade and station in Tables V-VII-Patchogue center's results.

A. Case II - Solutions

Recall that <u>Case 2</u> solutions deal with a situation in which management faces an over 12% <u>increase</u> in the demand for services (observed during May 1990). To address this demand problem, the solutions for the second scenario (Case 2) were derived through the application of Fox's (1966) resource allocation model. Since the model calls for the specification of a single objective function and a set of constraints, the solutions for this case were derived by specifying the number of matters waiting to be processed, as the objective function.

The results of this model's application can be found in <u>Table V.</u> A cursory examination of this table will reveal that 481 workers and a weekly payroll budget of \$230,756 are needed to achieve a steady state operational environment, for the new system services. The optimal distribution of these workers over the centers' stations can be found in Col. I, whereas the present (May 1990) staffing level by station is tabulated in Col. "G" of Table V. In other words, the (Fall 1989) weekly payroll budget of \$217,777 must be increased by approximately 6% and the staff level by 7.8% in order to meet the 13% increase in the demand for services. These figures include the 18 workers retained in the Patchogue Center for reassignment by management to other stations of the "new" CBA.

Table v CLIENT BENEFITS STUDY Case II Solutions

^{*}The structure of the chronic care unit used in this study is different from the actual structure. For explanation, see pp. 28-29 of text.

Re: The SCDSS Final Report

A comparison of Table V results against those found in Table III will reveal that the optimal staff allocation solutions are not identical inasmuch as the new system is not identical The same can be said about the optimal to the old structure. utilization indices found in these tables. Also, note that in Case 2 solutions, the number of items waiting in a queue (see been increased for several Col. has Nevertheless, in both Cases (1 & 2) the constraint regarding the total amount of time a matter spent in the system was met, inasmuch as the processing cycle of the case records was completed with 3.8 weeks or less.

B. Case III - Solutions

Case 3 solutions as was noted earlier deal with a situation in which the center's administrators of the new system face more than a 12% increase in the demand for services under a lean payroll budget configuration. To address this problem, the solutions for this third scenario (Case 3) were derived through a stepwise application of the resource allocation model. Since the model calls for the specification of a single objective function and a corresponding set of constraints, the solutions for this case were derived through:

- o The minimization of the length of queue of cases waiting to be processed first, and consequently;
- o The weekly payroll budget was specified as a second objective function to be minimized.

The results of this stepwise application of Fox's (1966) marginal analysis (or resource allocation) model, can be found in Table VI. A cursory examination of this table will reveal that at least 476 workers and a weekly payroll budget of \$239,085 are needed to achieve a steady state operational environment, under a lean payroll budget configuration and about a 13% increase in demand for services. In other words, the Fall 1989 weekly payroll budget of \$217,777 must be increased approximately 5.5% and the staff by 7.7% in order to meet the increase in the demand for services. Embedded in these figures is the "labor pool" found in the Patchogue Center. Notice again that these percentage increases in resource requirements are not identical due to non-linear relationships that exist between them, accentuated by the marginal analysis model.

C. Case IV - Solutions

Recall that <u>Case 4</u>-Scenario calls for deriving staffing solutions under a <u>reduced</u> weekly payroll budget situation which is <u>five</u> percent below the Fall 1989 configuration of \$217,777. To ascertain these solutions, Fox's (1966) marginal

^{*}See earlier footnote on page 29A-10, Table V.

analysis model was used to conduct a sensitivity analysis.

Under this restricted budget configuration, only 423 workers and a weekly payroll budget of \$206,707 are needed. However, under this reduced weekly payroll configuration, the CBA system can handle an arrival rate (of cases) which is 16% -18% below the most recent (May 1990) demand for services. Again, notice that included in these figures are the pool of workers found in the Patchogue center. This budget restriction may defeat the intent behind the provision of Public Assistance Services. Specifically, a reduced level of services may prevent the CBA from realizing its collective goal of assisting the clients to achieve a position of economic self-reliance.

The ramification of these findings is that the CBA's caseload will have to be reduced proportionally. Such a reduction, however is infeasible, unless the eligibility criteria and/or the legal definition of poverty are modified by both the N.Y. State and the federal legislative branches.

The impact of this budgetary restriction upon the CBA operation is presented in detail below, in Table VII. Under this budgetary restriction, Station No. 1, for example, can handle an arrival rate of 65 matters per week, as denoted in Table VII, Column "A", whereas the current (May 1990) arrival rate to that station is 79 matters (items) per week, as was denoted earlier in Table VI. On the other hand, Station 18 can handle no more than 589 items per week, whereas its most current (May 1990) weekly arrival rate is 706 items as was denoted in Table V. Also notice that the solutions presented in Table VII call for staff reduction (by grade) in certain stations. For instance, Station 2 optimal solution requires no grade 10 worker, whereas, Case 2 solution (found in Table V) calls for one grade 10 worker to be assigned to this station (No. 2).

D. Ramification of the Findings

Due to the CBA's queueing behavior, <u>Case 4</u> findings in particular, suggest that the CBA's caseload will have to be <u>reduced</u> proportionally. Such a reduction, as was noted above, is infeasible unless the eligibility criteria and/or the legal definition of poverty is modified by both N.Y. State and the federal government.

To overcome the problems associated with a reduced budget, one may argue that the SCDSS should consider exercising the option of reducing the quality of services provided [see Spottheim/Wilson, March 1990]. Alternatively, it has been argued by some parties that a <u>staff reduction</u> will merely prolong the amount of time clients will have to wait for

page 32

services. These options, however, are not feasible due to the system's queueing behavior and the client's perceptions regarding its operation.

As an Open Jacksonian Network, the CBA exhibits certain queueing behavior. As the station utilization index climbs above 0.92 the mean waiting time at a <u>single server station</u>, in particular, begins to grow exponentially. Not only does the mean waiting time grow dramatically but also the variability exhibited in the waiting time experienced by a matter at that station. This becomes especially pronounced when the utilization index exceeds 0.96, and an unstable queueing behavior occurs in a single worker station in particular. This instability is due to dramatic buildups of queued cases that take a long time to dissipate. This is a system behavior that clients will find intolerable.

While the disposition by this division of cases is carried out with less effort than the disposition of the Community Service's (CSA) cases, the CBA's clients need some special attention due to their social and economic isolation. A recent survey of clients receiving public assistance services revealed wide-spread client dissatisfaction with:

- o The length of time they must wait before receiving their approved services;
- o The number of meetings with workers;
- o The number of telephone conversations with workers;
- o The promptness with which the workers returned their phone calls; and
- o The length of time they wust wait in the office for scheduled appointments [Spottheim, April 1990].

These clients' perceptions reflect their concerns about their social and economic isolation. Therefore, a reduction in the quality of services and worker/client communication, in particular, may defeat the Public Assistance Services intent of assisting the clients to realize a state of economic self reliance.

Also, one may argue that to mitigate the budgetary problems, management should alleviate the staffing <u>slack</u> found in stations whose optimal staff utilization index is below 0.30, and the "labor pool" of 18 workers found in the (defunct) Patchogue Center, in particular. This argument, however, must be substantiated, because the work flow patterns between stations were captured during the Summer/Fall of 1989. Thus, the low optimal utilization index found in numerous stations

page 33

may portray the system operation during the <u>vacation</u> seasons of 1989. Also, since the new CBA was <u>not</u> in operation at the time of this analysis, a validation procedure must be carried out before any action to alleviate the system's slack is initiated.

Should this validation procedure indicate that much more than 18 workers must be reassigned to busy stations, then SCDSS may have to consider alternative staffing policies, to mitigate the unabated budget crisis and the concurrent rise in the Public Assistance caseload. Finally, should this procedure indicate otherwise, then management may have to release surplus workers found in the said labor pool, which was identified earlier (by station & grade) in Tables V-VII.

V. MISCELLANEOUS ANALYSES

In addition to the resource allocation analyses discussed earlier, descriptive statistical methods were used for the purpose of providing management with information concerning the:

- o Arrival rate of case records to the CBA's centers;
- o Inter-station case records transactions;
- o Case records processing cost; and
- o Error rate analysis.

A. The Arrival Rate of Case Records

The weekly arrival rate to the system as was noted earlier, reflects the client's demand of service related actions to be processed by the CBA's centers. In contrast, the weekly arrival rate to a <u>station</u> is the sum of case records arriving to that station from the "rest of the world" or from another station within the center for further processing. Since several stations are involved (sequentially) in processing a given case record, the arrival rate to a station is likely to be <u>higher</u> than the arrival rate to a center.

The results of the case record arrival <u>rate</u> analysis are presented below in <u>Table VIII</u>. These results are tabulated in terms of <u>hourly</u> arrival rate of cases identified by their respective program's code to each of the "old" CBA's centers.

For instance, the hourly arrival rate of ADC's cases to the Islip, Coram and Smithtown Centers is 29.38, 13.67, and 18.96 respectively. In contrast, the hourly arrival rate of administrative matters (ADMN) to these centers is 15.33, 41.80, and 17.27 respectively. On the other hand, the Islip

^{*} Observed in the Fall of 1989. Recent data (May 1990) seem to indicate a 13% increase in the arrival rate of case records to the system.

page 34

Center's arrival rate of HR, MA and FS cases is 11.17, 1.50, 17.88 and 4.85. The center's weekly arrival rates of case records can be estimated through the multiplication of their respective hourly arrival rates by 35.5

It should be noted that the variation of arrival rates across centers is partially reflected in the center's staffing needs. Another factor influencing the centers staffing needs, as well as its processing cost, is the intensity of case record transactions.

B. Case Records: Transactions and Processing Costs

The case record transactions index, or multiplier, denotes the average number of transfers between the stations involved that a case record (entering a given center) ought to go through for processing purposes [Spottheim 1975]. Embedded in this index are repeated "visits" of a case record to a The multipliers for the old CBA's system are presented by program and center in Table IX-A. An examination of this table (IX-A) will reveal that the ADC, MA, and FS cases' multipliers of the Islip Center, for example, are 3.64, 7.26, and 3.09 respectively. On the other hand, the Islip, Coram and Smithtown Center's multipliers with respect to the ADC's cases are 3.64, 4.59 and 4.83 respectively. that the MA cases' multipliers of the Islip, Smithtown and Riverhead Centers have a numerical value which is greater than seven, whereas, the HEAP's multiplier of the Huntington Center indicates that the average number of transfers for a HEAP case is 14.

Recall that the transaction index has a bearing upon the case record's processing cost. Hence, the higher the multipliers' value, the more expensive it is to process the case record. The processing-cost information, concerning the old CBA's system is tabulated by program and center in Table IX-B. By comparing the <u>cost</u> information found in this Table (IX-B) against the multipliers found in Table IX-A, inferences about the relationships between the multiplier and the processing cost can be drawn. For example, the high processing cost (\$36.21) of HEAP cases observed in the Huntington Center can be partially attributed to the high value of this program's multiplier (14.00) found in this center. In contrast, the <u>low</u> processing cost of administrative matters (ADMN) across all centers can be attributed to the low multiplier value of these matters.

C. The Error Rate Analysis

The error rate analysis was conducted in response to the center administrator's request. Subsequently, the data collection form was redesigned so as to allow us to collect

page 35

concurrently (in the Fall of 1989) a 100% sample of error rate and work flow data concerning the <u>old</u> CBA operation. The results of this analysis have been tabulated under the following headings:

- o Program number;
- o Matter's number;
- o Error-Causing Station;
- o Error Rate; and
- o Number of Occurences.

The program's name, code and number were listed earlier on page 21, whereas the matters have been defined in Table I (p. 21A-1). On the other hand, the error-causing stations' name and number can be found in Table II (p. 26A-1).

The findings of this analysis are presented under the above mentioned headings in <u>Table X</u>. The error rates denoted in <u>Table X</u> are defined as the probability that the indicated error-causing stations are likely to enter erroneous program and matter-related information into the case records. Hence, an error rate of 1.00 indicates that the corresponding station has entered erroneous information into each case it processed, whereas an error rate of 0.1 implies that the station in question has entered erroneous information into 10% of the cases it processed.

For expository purposes let us examine Station No. 140 (i.e., Mastic Center's-Undercare Clerk) findings. This station's error rate is 0.9762. That is to say that of the 42 cases processed by this station, 41 cases were found to have erroneous information regarding matter No. 15 (Undercale-Case Record Processing) and Program No. 1 (ADC) as indicated in Table X, Col. 5 (# of occurences). Also, notice that most of the detected errors are associated with:

- o Program 1 (ADC) matters 5, 15, 16; and
- o Program 4 (MA) matters 5, 10, 15.

Finally, since the designated detecting stations returned the erroneous cases to the error-causing stations for correction, the staffing allocation results, presented earlier, <u>do</u> take into account the time spent by stations involved in detecting and correcting the errors.

Re: The SCDSS Final Report

Chapter Five THE COMMUNITY SERVICES ANALYSIS

The Community Services Administration (CSA) administers a host of mandated social service programs. As the local delivery system, this Division offers direct services and arranges for the provision of services by a third party. The avowed intent of these services is to assist families, children and individuals who face distressful situations or personal handicaps to attain and sustain a socially secured environment and self-reliancy [Adopted from Wedemeyer 1970]. This intent and the corresponding goals have affected the operational structure this organization which is composed of Bureaus such as: a) Child Protective Services, b) Adult Services, c) Central Office and d) Family & Child Services.

I. THE CSA'S GOALS, STRUCTURE AND PRODUCTS

While the CSA is characterized by its enduring operational structure and recurrent work flow patterns, it was postulated earlier in this report, that this Division's missions and goals influenced its current operational structure and administrative processes. Specifically, the CSA's Bureaus along with their corresponding stations and the work flow patterns between these stations have been created by management, to assure an orderly determination of clients' eligibility and the provision of direct or indirect services to the eligible.

A. The CSA's Goals

As the social service delivery arm of the SCDSS, the CSA's mission is to administer a variety of programs whose targeted populations are: a) needy adults, b) children at risk, c) children in need of placement, and d) intact and single-parent families and which are in need of services. The goals of this Division, according to management, are to:

- o Investigate reports of abuse, neglect or maltreatment of vulnerable adults and children;
- o Petition the court for guardianship and to serve as the conservator or the guardian of theses adults and children, as well as providing them with remedial services;
- o Provide residential placement service to mentally or physically handicapped adults;
- o Provide a variety of homemaker services to the frail, physically disabled and elderly adults in particular and to the medicaid program's clients

generally;

- o Render home management and health related services to mentally and physically handicapped adults;
- o Help eligible individuals and families to find housing;
- o Strengthen the bond between related individuals to enhance their options of living together;
- o Provide foster care services to neglected, abused and other children in need of supervision;
- o Secure an adoptive home for children in need of such a service;
- o Provide day care services to eligible parents, to allow families to become self-supporting;
- o Provide preventive services to eligible intact families and single parents for the purpose of strengthening the family unit and mitigating the risk of placing these clients' children in foster homes; and
- o Provide counseling and referral services to teenage clients.

These goals are realized by a set of services and administratively related actions taken by the CBA, on behalf of the clients, for the purpose of changing their social, economic or health status.

B. The CSA's Operational Structure

Recall that the management science approach used in this analysis presupposes that the CSA's Bureaus can be viewed as a "queueing network" of stations, which are linked together by a recurrent flow of items (matters) that must be processed, sequentially. Since the conventional organizational structure of this Division did not identify such stations, it was necessary to disaggregate the Bureaus into their respective sets of work stations. The disaggregated CSA stations are listed in Table XI. An examination of this table will reveal that it also contains information regarding the average labor cost per minute for each of the 153 stations.

C. The CSA's Products

While the actions mentioned above are the means by which this

csasta

system's stations realize the CSA's goals, such information was not readily available, inasmuch as the CSA's administrative data base was confined to information such as: a) caseload, b) number of clients seen and c) number of cases processed. Since the CSA system has been viewed as an open queueing network of stations, the available information was deemed to be inappropriate for this analysis.

Consequently, we have defined an exhaustive set of administrative actions taken by this system, in relation to their clients. These actions, as noted earlier, are also referred to as: a) common flow items, or b) service and management-related matters.

The work flow patterns of these matters enabled us to estimate the cumulative time devoted by stations involved, directly or indirectly, in the provision of services. Specifically, by "tracing" the flow of matters between stations, quantitatively, we were able to emulate situations in which "actions" related to service administration were initiated in one station and transferred to other stations for further processing, and subsequently returned to the originating station.

It should be noted however, that unlike the CBA's stations which specialize in the processing of a particular matter, the CSA's stations involved tend to process the same matter, sequentially.

These matters are listed in <u>Table XII</u>. A cursory examination of this table will reveal that it contains a list of 450 distinct service and administratively related matters. Also, the Bureaus "visited" by the matters are identified in this table by an <u>asterisk</u> (*).

II. AN OVERVIEW OF THE CSA ANALYSIS

Social and human service delivery agencies are known to have multi-objectives (or goals) rather than a single objective, such as minimizing the client's waiting time. In light of the county budget crisis, it was felt that the most appropriate objectives are the following:

- Assure that service-related matters which involve emergency situations, and/or clients waiting for service, will be processed immediately;
- o Minimize the waiting time a matter must spend in a station before being processed; and
- o Minimize the weekly payroll budget expenditure.

Re: The SCDSS Final Report

To assure that the first condition is reflected in the model's results, all emergency matters were assigned a <a href="https://www.numerical.com/distance-numeri

Thus, the CSA staffing allocation solutions were derived through a "stepwise" application of Marginal Analysis model. In applying this model, the CSA was viewed as an open queueing network, inasmuch as the bureaus have no control over the weekly arrival rate of matters to the system.

A. The Data Base

To obtain these solutions through the application of the said model, we have used a data base containing the following information:

- o Work standards (or work efforts);
- o Weekly arrival rate of matters to Bureaus and consequently to the station;
- o Work flow patterns of matters between stations;
- o Workers' performance flexibility (exchangeability) matrix;
- o Estimated weekly payroll by station; and
- o Current staffing by station.

B. The Scenarios

Recall that the research problems mentioned in Chapter I were addressed through the application of management science techniques for the purpose of finding optimal resource (payroll budget& staffing) allocation solutions under various operational scenarios. In light of the county's financial problems, these solutions were derived through the application of the "minimum cost" computational procedure. For expository purposes, however, the results presented in this Chapter are confined to three scenarios, hence:

know how the Fall 1989 level of factors of production (e.g., weekly payroll budget and staff) should be distributed over the CSA's stations, thereby allowing this system to process a weekly arrival rate of services and administrative matters, observed during the Fall of 1989, in the most efficient manner.

- Case 2 provides steady state solutions for a situation in which management wishes to know the optimal distribution of staff members over the stations so as to allow this system to process efficiently, a 10% increase in the weekly arrival rate of matters.
- case 3 provides steady state solutions for a situation in which management wishes to know the: a) amount of matters that can be processed (per week) under a restricted weekly payroll configuration which is five percent (5%) below the Fall 1989 weekly payroll budget, b) the corresponding amount of staff members needed to process the said matters, and c) the optimal distribution of workers across all stations of the CSA system.

We mean by "steady state solution" in the foregoing, a solution to a system whose defining parameters are <u>stable</u> and predictable in a statistical sense. We do not mean a system that has been rendered deterministic; rather, the variability has been modeled (accounted for) explicitly. Finally, the reader should note that solutions for the scenarios were derived through the application of the "minimum cost" procedure.

C. Modeling Methodology

Since the Marginal Analysis Model calls for the specification of a <u>single</u> objective function and numerous constraints (i.e., operational rules), the minimum cost solutions for scenarios 1 & 2 were derived through a <u>stepwise</u> application of this model. Specifically, these solutions were derived through the specification of the:

- o Waiting time a matter must spend in a station as the <u>first</u> objective function; and
- o Weekly payroll budget as the second objective

function to be minimized.

Subsequently, the constraints or rules of operation were specified to:

- O Utilize to best advantage the existing workers' performance flexibility, thereby allowing us to transfer workers from a given bureau's station to any other station of the system;
- o Mitigate congestion problems found in supervisory and other stations;
- o Assure that the amount of time spent by a matter in the system is no greater than <u>four</u> weeks; and
- o Assure that service-related matters which involved emergency situations, and/or client waiting for services, are <u>processed</u> immediately.

These rules were incorporated into the model to assure that the system's productivity enhancement would be achieved without <u>tampering</u> with the: a) work standards, b) organizational structure and c) work flow patterns as indicated by actual observation of the system.

Therefore, we assumed that the processing capacity of a station can be expanded by increasing the number of workers at that station. On the other hand, workers affiliated with a station whose utilization index was found to be <u>low</u>, were <u>transferred</u> to congested stations, when possible, as indicated by the worker interchangeability matrix. The quantity of workers added to a <u>congested</u> station was determined by taking into account the number of workers necessary to minimize the waiting time a matter must spend at the station, as well as the number of additional workers that may be required to assure that matters needing actions at the station will clear the system in four weeks.

III. THE CSA'S STAFFING SOLUTIONS

The scenarios (or cases) mentioned above, represent a sample of administrative situations that have been analyzed through the application of the queueing and marginal analysis models, without altering the CSA's: a) observed work standards, b) operational structure and c) work flow patterns.

The application of these models enabled us to generate descriptive and prescriptive information concerning this system's performance. Specifically, these models allowed us to generate a uniform set of numerical information (by station) for each scenario; namely the:

- Station code
- 1. Weekly arrival rate (of matters) to station
- 2. Weekly service (or processing) rate per worker by station
- 3. Present utilization index
- 4. Optimal utilization index
- 5. Average waiting time a matter spends in a station before being processed (measured in weeks)
- 6. Worker's grade
- Present staffing (by worker's grade)
- 8. Staffing after shift
- Optimal staffing (by grade)

It should be noted that a zero value for any of these items indicates that they were not calculated, due to the lack of data concerning the station in question.

A. Case 1 - Results

Solutions for Case-1 are tabulated by bureaus, in <u>Table XIII</u>. A cursory examination of this table will reveal that it contains 9 columns of numerical information concerning the solution's items listed above. A further examination of this table will reveal that the system requires at <u>least</u> 424 workers and a weekly payroll budget of \$246,503 in order to achieve a steady state operational environment. In contrast, this system would require over 465 workers under the conventional staff allocation practices. However, the Fall 1989 staffing level was 384 workers, and the corresponding weekly payroll budget was \$221,698.

Also, notice that the optimal staffing is vastly different from the present staffing. For instance, the present staffing for station No. 15 is composed of 37 grade 19 workers, and 8 grade 17 workers, whereas the optimal staffing solution calls for 18 grade 19 and 8 grade 17 workers. Therefore 19 grade 19 workers were transferred to other stations. Also, notice that upon transferring these 19 workers (to other stations) the optimal utilization index was raised to .988 (from the present index of .571), without affecting the average waiting time a matter must spend before being processed. This average is .049 of a week or 105 minutes. A comparison of the current utilization against the optimal indices will reveal that the latter indices have a higher value than the former. Ideally, the optimal indices should have a range of 0.55 to 0.90.

Some stations, however have a current utilization index which is greater than one. For example, the current staffing of station No. 20 causes congestion in that station, due to a very high "present utilization" index (2.343). This high

present utilization index indicates that this station requires a staff of 8 persons, rather than the current 3 workers, to operate in a steady state operational environment, as was denoted above in Table XIII, Col. I & G, respectively.

Moreover, numerous Adult Services' stations are congested inasmuch as their present (Fall of 1989) utilization index is greater than one. For instance, the present utilization index of Station 28 is 1.590. By hiring an additional worker, this index was reduced to .795. In this instance, it was necessary to hire a new worker because the worker exchangeability matrix allows for no transfer of workers to this station. In addition, it was found that many of the Family/Child Services' stations are also congested. To reduce congestion, it was necessary to transfer and/or hire workers.

To mitigate problems of congestion, workers were transferred from stations where utilization indices were found to be low. In fact, several stations were found to have zero arrival rate, due to insufficient work flow data. For example, Adult Services' stations, Nos. 48-50, show a zero arrival rate of matters, due to lack of data. Hence, workers affiliated with these stations were transferred to other, congested stations. However, these stations can be restaffed by management "retransferring" workers from stations where staffing is greater than 10 persons. In other words, the system has enough "slack" to reassign workers.

Finally, notice that the optimal resource allocation model used in this analysis tends to equalize the work load of the stations' and matters' waiting time through the reassignment of the least staff to the busiest stations. The criteria of reassignment of staff members have been specified in the staff exchangeability matrix.

B. Case II Results

Recall that Case 2 provides a solution for a situation in which management faces a 10% increase in the demand for services. The solutions for the second scenario (Case II) were also derived through a stepwise application of the resource allocation model.

The results of this stepwise application of the model can be found in <u>Table XIV</u>. A cursory examination of this table will reveal that at least 452 workers and a weekly payroll budget of \$262,131 are needed to achieve a steady state operational environment, under a <u>lean</u> payroll budget configuration.

Table XIV Case II Results

1.:

A comparison of Table XIV results against those found in Table XIII will reveal that the optimal staff allocation solutions are not identical, due to the 10% increase in the arrival rate of matters. For example, Station No. 2 requires 3 workers rather than 2, as was denoted in Case I Solution (Table XIII) because the arrival rate to this station increased from 104 to 114 cases. The same can be said about Station No. 15. Under this scenario, this station needs 21 grade 19 workers and 8 grade 17 workers, whereas Case 1 Staffing solution calls for 18 grade 21 and 8 grade 17 Workers.

Finally, due to the nonlinear relationships that exist between resources and demand, the proportion increase in the demand for service (manifested in terms of arrival rate to the stations) is not identical to the proportional increase in the resource needs. The demand for services in this instance was increased by 10% whereas the payroll budget and staffing needs were increased by 6% & 6.3% respectively, over Case I Solutions.

C. Case III Results

Recall that Case III-Scenario calls for deriving solutions under a highly restricted weekly payroll configuration which is 5% below the Fall of 1989 budget. To ascertain these solutions, the model was used to conduct a <u>sensitivity analysis</u>. The solutions for this scenario are tabulated in Table XV.

Under this <u>restricted</u> budget configuration, <u>only</u> 361 workers and weekly payroll budget of \$210,098 are needed. However, with these restricted resources, the CSA's system can process an arrival rate of matters which is 16.7% <u>below</u> the Fall of 1989 arrival rate. Hence, Station No. 1, for example, can handle an arival rate which is no more than 21 matters per week, whereas during the Fall of 1989 arrival rate of that station was 26 matters (items) per week, as was denoted in Table XIII. On the other hand, Station 15 can handle no more than 1,334 items per week, whereas the 1989 arrival rate was 1,602 as denoted earlier in Table XIII.

Notice that the solutions presented in Table XV call for staff reduction (release) in certain stations. Hence, several staff members affiliated with stations whose arrival rate is $\underline{\text{zero}}$, were released because no $\underline{\text{workers}}$ $\underline{\text{exchangeability}}$ (or transfer) information was available for these workers.

Re: The SCDSS Final Report

page 45

For example, one <u>grade 19</u> worker has been released from Station No. 21. Similarly, one <u>grade 10</u> worker has been released from Station No. 23.

Also, notice that the average waiting time of matters for all, <u>but</u> Stations 43, 54 and 112 seem to be reasonable. The expected waiting time of matters at these stations exceed a period of one week.

Finally, the 5% decrease in the payroll budget (of 1989) calls for a 6.3% reduction of the Fall of 1989 staffing level as well as a concurrent 16.7% reduction in the arrival rate of matters to the system. Finally, notice that these percentage decreases are not identical due to non-linear relationships that exist between them, accentuated by the marginal analysis model.

D. Ramification of the Findings

The findings seem to indicate that the weekly number of requested services and administratively related matters demanded, rather than the caseload, or number of clients seen should be used to indicate workload because it can be used to ascertain the entire workflow pattern or transactions associated with the processing of a given case record. These transactions reflect both repeated visits and serial flow of matters between stations. In other words, this recursive processing of matters implies that a service or a clientrelated action (matter) initiated in one station could be transferred (serially) to other stations for processing and subsequently be returned to the originating Since each of these transfers is regarded as a transaction, several stations may contribute to the cumulative processing effort (measured in minutes) of a given matter.

Since this Division is composed of a network of stations engaged in a sequential processing of matters, the ratios of supervisor/workers and clericals/supervisor are not constant. Rather these ratios are influenced by the <u>frequency</u> a matter must visit a given station for processing purposes.

The study also revealed that several supervisory and worker stations are overburdened by the amount of service and administratively related matters they must handle while related downstream stations are not receiving work as freely as they should. This administrative paradox can be attributed to the prevailing practice in which supervisory stations, in particular, tend to be involved in non-supervisory functions by acting as:

- o Substitute Worker;
- o Monitor;

Re: The SCDSS Final Report

page 46

- o Auditor; and
- o Referral Unit.

This problem, however could be mitigated through the:

- o Establishment of shorter supervisory span of control through the creation of new positions such as lead worker and assistant supervisor;
- o Streamlining the daily operation of the programs through the identification of specific tasks associated with the processing of the various matters or products and reassigning to workers some of the tasks currently carried out by supervisors; and
- o Assignment of certain matters currently processed by the supervisors to the newly created positions of lead worker and assistant supervisor.

IV. MISCELLANEOUS ANALYSIS

In addition to the staffing allocation analyses presented thus far, descriptive statistical methods were used for the purpose of providing management with information concerning the:

- o Arrival rate of matters;
- o Processing cost of matters; and
- o Inter-station matters transaction.

A. The Matter Arrival Rates

Recall that the matters arrival rate to the CSA's System reflects the weekly demanded level of services. The weekly arrival rate to a station on the other hand, is the sum of matters arriving to that station from the "rest of the world" and from other stations of the system. Since several stations are involved in the processing of a given matter, the arrival rate to a station tends to be higher than the arrival rate to the system.

The weekly number of arrivals to <u>all</u> stations of the system are tabulated by <u>matter</u> in <u>Table XVI</u>. It should be noted that these arrivals do <u>not</u> reflect the level of services demanded from the CSA; rather, they denote the sum of the input and throughput of matters.

A cursory examination of this table will reveal that these arrivals are grouped by program and generic matters. Also, the four columns of information found in this table denote the following:

Re: The SCDSS Final Report

- o The present (May 1990 Estimation) arrival rate;
- o A 10% increase in the (May 1990) arrival rates;
- o A 20% increase in the (May 1990) arrival rates; and
- o A 10% decrease in the (May 1990) arrival rates.

B. Matter Transaction and Processing Cost

The transaction (or multiplier) index as was noted earlier, denotes the average number of transfers a matter must go through for processing purposes. In other words, the multiplier denotes the average number of stations a matter must "visit" for processing purposes.

The transaction index has a partial bearing upon the matter's processing cost. Specifically, a high transaction index implies that numerous stations are involved in the processing of the matter in question. Therefore the cumulative effort devoted to process that matter as well as its processing cost, are likely to be higher than a matter whose index has a low value.

The processing cost and the corresponding transaction index are tabulated by matter in Table XVII. An examination of this table will reveal that it contains two columns of numerical information entitled: a) cost and b) number of stations The numerical values listed under the heading "visited." "number of station visited" are the transaction indices. For example, the cost of processing matter No. 1 is \$2.51 whereas, its multiplier has a value of 2.012. That is to say that matter Number 1 was processed on the average, by 2.012 Finally, it should be noted that a few matter's stations. codes appearing in Table XVII have no corresponding matter's names. Although these codes were erroneously specified during the data collection phase, they were included in this study as a "catch all" for other matters processed by the system.

C. The Weekly Arrival Rate to the System

Recall that the weekly arrival rates denoted earlier in Table XVI are composed of both the input and throughput to the system. Specifically, each of these weekly arrival rates is the sum of:

- o The <u>direct</u> input of a matter from "the rest of the world" (ROW) to the CSA's systems; and
- o The internal (or indirect) input of a matter arriving to a given station from other stations of the system.

Re: The SCDSS Final Report

page 48

Therefore, a <u>double</u> counting exists in these rates. To estimate the weekly arrival rate to the system or the demand for services, one must divide the arrival rates found in Table XVI by their corresponding multipliers.

The arrival rate of matter No. 1 to the <u>system</u> for example, can be estimated by dividing this matter's number of arrivals found in Table XVI, by this matter's multiplier denoted in Table XVII, (296/2.012=147). Thus, Matter No. 1's weekly arrival rate (or direct input from ROW) to the system is 147. On the other hand, the arrival rate of matter No. 4 to the system is (355/2.277=156), whereas matter No. 27's arrival rate to the system is (388/2.727=142). These estimated figures, in essence, reflect the level of services and administratively related actions demanded from the CSA.

page 49

Re: The SCDSS Final Report

Chapter Six SUMMARY & CONCLUSION

I. INTRODUCTION

This study was conducted for the purpose of providing administrators, supervisors, and workers alike with a unified perspective regarding the SCDSS operation. The work standards, performance indices and the resource allocation solutions generated by this study were developed in consideration of the federal, state and local governments' desire to improve the productivity of the Public Assistance and Social Services Programs. While this report emphasized the logic and reasoning behind the management analysis, its models were used as "decision support tools" to address the impact of "what if" scenarios, thereby avoiding a costly experimentation with alternative operational structures for the SCDSS.

The theoretical framework behind this research study is a blend of classical organization theory and management science techniques. Hence, the Client Benefit (CBA) and the Community Service (CSA) Divisions of the Suffolk County Department of Social Services were viewed as two separate service delivery organizations. Specifically, these Divisions were viewed as two mutually exclusive open queueing networks composed of processing stations which are engaged in recurrent administrative procedures to assure, on behalf of their clients, the processing of identifiable client and administratively related matters.

Since the term "organization" implies the existence of enduring organizational structure, administrative processes and recurrent work flow patterns [Bausky 1977], these Divisions were disaggregated into their organizational components (stations), and service-related matters processed by these stations were identified. Subsequently, data concerning the work effort devoted to process a particular matter by each of the stations, and the work flow patterns of matters, along with other data, were collected and processed in conjunction with the queueing theory and Fox's (1966) Marginal Analysis technique, for the purpose of addressing a major managerial predicament faced by the CBA and CSA Divisions, namely:

o What is the best composition of resources (i.e., payroll budget & employees) that would lead to a situation whereby these service delivery systems will "produce" an anticipated level of outputs associated with their program's mandated missions,

without altering the: a) observed processing time of various matters by their respective processing stations, b) the operational structure of these Divisions and c) the work flow pattern between their stations.

II. THE METHODOLOGY

address this managerial problem, we have used amalgamation of discursive social services and organizational theories, along with management science techniques. In using this approach, the CBA and CSA were perceived to be composed of two "Open Queueing Networks" of stations linked together through the recurrent flow of matters. Hence, given the observed or desired processing levels of matters or cases per week (under alternative scenarios), the intent behind the application of Fox's (1966) Marginal Analysis Model was to determine the optimal number of workers needed for allocation to each of the stations. The CBA and the CSA's staff allocation solutions provided by this model were derived in context of the case record and matter processing activities, respectively. In applying this approach, an objective function and a set of resource allocation rules were embedded into the computer models to:

- o Minimize the waiting time a matter must spend at a station before being processed;
- o Utilize to best advantage the workers' performance flexibility;
- o Minimize the overburdened workload of busy stations; and
- o Assure that the total amount of time spent by a matter in these systems is <u>no</u> greater than four weeks.

In using these rules we tried to find the overall level of an efficiently allocated payroll budget necessary to meet an administrative performance measure based on the timely disposition of service related matters.

It should be noted that the optimal resource allocation models used in this analysis tend to equalize the workload of the stations' and matters' waiting time through the reassignment of the least busy staff to the busiest stations. The criteria of reassignment of staff members have been specified in the staff exchangeability matrix.

A. Information Generated

The application of this methodology allowed us to generate a uniform set of results (by station) concerning the <u>efficiency</u> <u>aspects</u> of the Client Benefit (CBA) and the Community Services (CSA) Divisions' operation, namely:

- The CBA & CSA systems' demanded level of services;
- o The processing capacity by station;
- o The time and cost of processing a given client and administratively related matters by each of the stations involved (i.e., work standards);
- o The number of matters (items) waiting to be processed by a given station along with the amount of time spent by an item (or a matter) while waiting to be processed by that station;
- o Productivity indices regarding the current and latent level of staff utilization in each station;
- o Optimal distribution of staff members across the stations of the systems;
- o Estimated "production" levels (of matters) and corresponding staff requirements (by station) under alternative administrative scenarios; and
- o Estimated payroll budgets under alternative financial resources constraints.

Subsequently, these indices and measurements were used to draw inferences regarding the system operation and to suggest remedial actions to enhance the performance and productivity of these Divisions.

B. Limitation of this Study

Although it is recognized that a performance study should address both the efficiency and performance aspects of service delivery [Cordry & Tuttle 1984], this applied study deals with the <u>efficiency</u> aspect only. Therefore, this study does have certain <u>limitations</u>. By dealing with the <u>efficiency aspect</u> of the allocation of resources (i.e., staffing and payroll budget) within the SCDSS, the study <u>ignores</u> service delivery issues such as the:

o Client/worker relationships;

- o Effectiveness of the services rendered by this department;
- o Clients' satisfaction with the services rendered by the CBA and CSA segments of this department; and
- o Quality of the services rendered.

III. INFERENCES DRAWN

Since the operation of these Divisions is not intuitively obvious, the application of this management science approach allowed us to gain a better understanding of the systems operation. Also, this approach allowed us to address the issue of efficient utilization of workers, without tampering with the observed work standards. Inferences drawn from this and related studies are as follows:

- The queueing network behavior exhibited by these service delivery systems precludes the application of a conventional management analysis. Therefore, a management science approach should be used to:

 a) resolve the work overburden and low work intensity problems found ir certain supervisory and worker stations, b) accelerate the work flow velocity, and c) allocate the necessary resources (by station) so as to achieve a timely disposition of a given (or desired) volume of service and related administrative matters;
- o Since these Divisions are composed of queueing networks of stations engaged in a sequential processing of matters, the ratios of supervisor/workers and clericals/supervisor are not constant. Rather these ratios are influenced by the frequency a matter must visit a given station for processing purposes;
- The supervisory stations found in the CSA system in particular, are overburdened by the amount of service-related matters they must process;
- o The busy supervisory stations of the CBA in particular, tend to handle multiple non-management functions such as: a) substitute worker, b) monitor, c) auditor, and d) referral units;
- o Although numerous workers were shifted from their customary stations to busier ones, the model's solutions call for hiring new workers to handle the increased demand for services. Thus, the CBA needs

7.8% additional workers, whereas the CSA requires an increase of 10.4% over the Fall of 1989 staff levels;

- o Due to the queueing behavior exhibited by the CBA and CSA systems, a <u>five percent reduction</u> in their Fall 1989 budget will cause dramatic buildups of clients waiting for services;
- o Since such a queue (of clients) may never dissipate in a situation of increasing demand for services and a simultaneous reduction in labor forces, clients, workers and politicians alike may find this situation intolerable; therefore the SCDSS may have no other recourse but to increase the number of hours its staff must work per week;
- Management should continue the policy of rewarding workers who: a) acquire diversified, rather than specialized skills and b) are willing to take additional responsibilities, thereby enhancing the flexibility and consequently the efficiency of the CBA and CSA operation;
- o The inter-center (and inter-bureau) mail distribution should be carried out at least <u>four</u> times a day, thereby "smoothing" the work flow between stations, and consequently minimizing the waiting time a matter must spend before being processed; and
- o Vacation leave should be scheduled by staff ahead of time. It should be spread over the entire year in such a way that no more than 10% of staff members are out at any given time.

IV. RAMIFICATION OF THE FINDINGS

In light of the budget deficit faced by Suffolk County, it has been advocated by concerned parties that the SCDSS should consider the options of: a) reducing the level of services provided to its clients, b) staff reduction which seemingly will merely prolong the waiting time for services and c) alleviating the staffing slack found in (numerous) stations whose optimal staff utilization index is below 0.30. These options, however, are not feasible due to the:

- o Steady and unabated rise in the mandated program's caseload;
- o Clients', workers' and politicians' diverse

perceptions regarding the consequences of these options;

- o Legal regulations mandating service caseloads and clients' limited waiting time for services;
- o System's queueing behavior; and
- o Fact that the work flow data collected during the Summer/Fall 1989, may reflect a vacation season slowdown of activities; therefore the slack level found in the systems may not be sufficient to alleviate the consequences of anticipated staffing shortage, and budget cuts.

Thus, to mitigate the unwarranted consequences of a budget reduction and the simultaneous rise in the Public Assistance and Social Services Programs' caseload [see Pear, R. in the N.Y. Times August 20, 1990], the SCDSS may have no other recourse but to consider staffing and management actions which are beyond the scope of this study. Such actions could include the:

- o Establishment of a shorter supervisory span of control, through the creation of new positions such as lead worker and assistant supervisor for the CBA's Division, in particular;
- o Streamlining the daily operation of the programs through the identification of specific tasks associated with the processing of the various matters and reassigning some of the tasks currently carried out by the CBA's supervisors to their workers; and
- o Assignment of certain matters currently processed by the CBA's supervisors to the newly created positions of lead worker and assistant supervisor;
- o Implementation of the "work partitioning" practice in which the higher grade workers would be involved, primarily, with decision making, whereas the lower grade workers would handle preliminary intake activities and subsequent follow ups. A hierarchical worker management organization would be required to effectively implement this practice;
- o Implementation of a "scheduling arrivals" or an appointment scheme in order to even the workload and minimize workload variability, thereby mitigating the congestion problems found in these systems;

- o Creating "multi-purpose worker" positions to handle caseload variability across all programs. Such workers should be able to handle a spectrum of responsibilities to mitigate the negative impact of work "surges." If the surges cannot be handled by these workers, over-time should be allowed, inasmuch as it is less costly than hiring new workers;
- o Implementation of a longer work week. Although labor will translate this policy as a pay rate cut, it is an alternative that will save jobs; and
- o Improving the computerized data base system, thereby allowing workers to track clients and to gather the necessary information concerning services and administratively related matters associated with the clients.

Finally, it should be noted that these suggested actions will not remedy the situation. Rather, they will merely mitigate a few of the unwarranted consequences that might be caused by the unabated rise in the mandated programs' caseload and the concurrent reduction in the payroll budget of this Department.
